Data storage in distributed systems - part II

Piotr Jaczewski
RTB House

What will this lecture be about?

In this part of the course we will focus on NoSQL databases and their usage in distributed systems. We will also briefly talk about data formats and their features from the perspective of a distributed system.

We will cover the topics of:

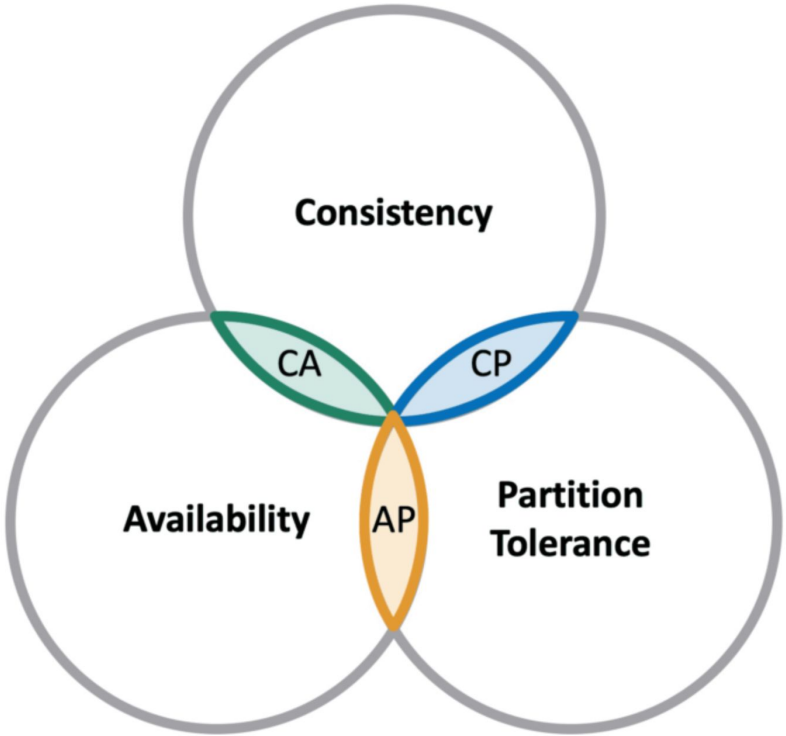
- Data models in NoSQL storages.
- Implementation details of selected NoSQL storages.
- Data formats and schema evolution in distributed systems.

NoSQL Databases

Some of the common features of the NoSQL databases:

- Designed to easily scale horizontally.
- Usually don’t use strict schemas.
- Concentrated around data aggregates.
- Don’t use SQL, but some have query languages.
- Mostly support limited transactional capabilities (like multi-object transactions), due to running on clustered environment.
- Provide various options for data consistency.

CAP Theorem



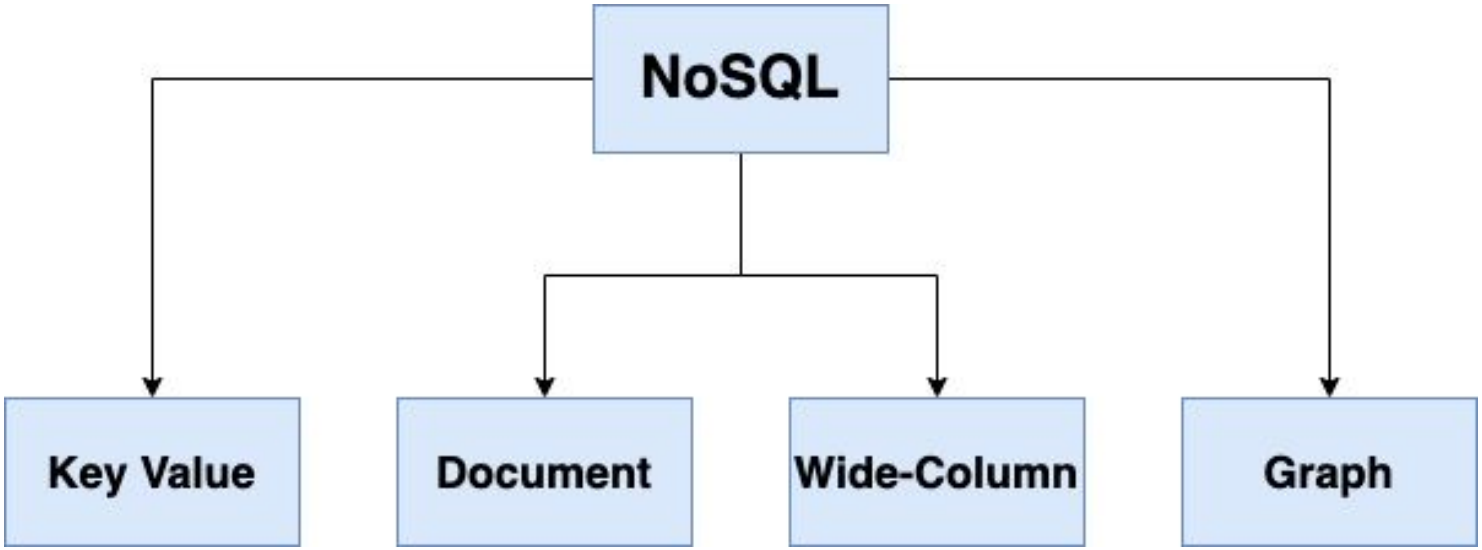
Source: hazelcast.com

CAP Theorem - critique

A great article by Martin Kleppmann:

https://martin.kleppmann.com/2015/05/11/please-stop-calling-databases-cp-or-ap.html

NoSQL Data Models



Key Value Model

- May be viewed as a generalization of a hash table with put/get/remove operations.
- Data type agnostic - the understanding of stored value is the responsibility of client applications.
- Some implementations may include some built-in data types like maps, sets, counters.
- None or limited querying capabilities.
- Offer great performance.

Document Model

- Can be considered as a subtype of key-value databases.
- Have some awareness of the data stored.
- The document format is usually JSON, BSON, XML, etc.
- The documents doesn’t have to be of the same schema in a table/collection.
- Slightly improved querying capabilities.
- Support for secondary indexes.
- Allow partial document update.

Wide-Column

- Another variation of key-value model.
- No relations between tables.
- Map keys to rows and rows consist of groups of columns.
- Groups of columns are called column families.
- Usually each row may have a varying number of columns.
- Some implementations feature SQL-ish query language.
- Nonexistent columns do not take storage space.

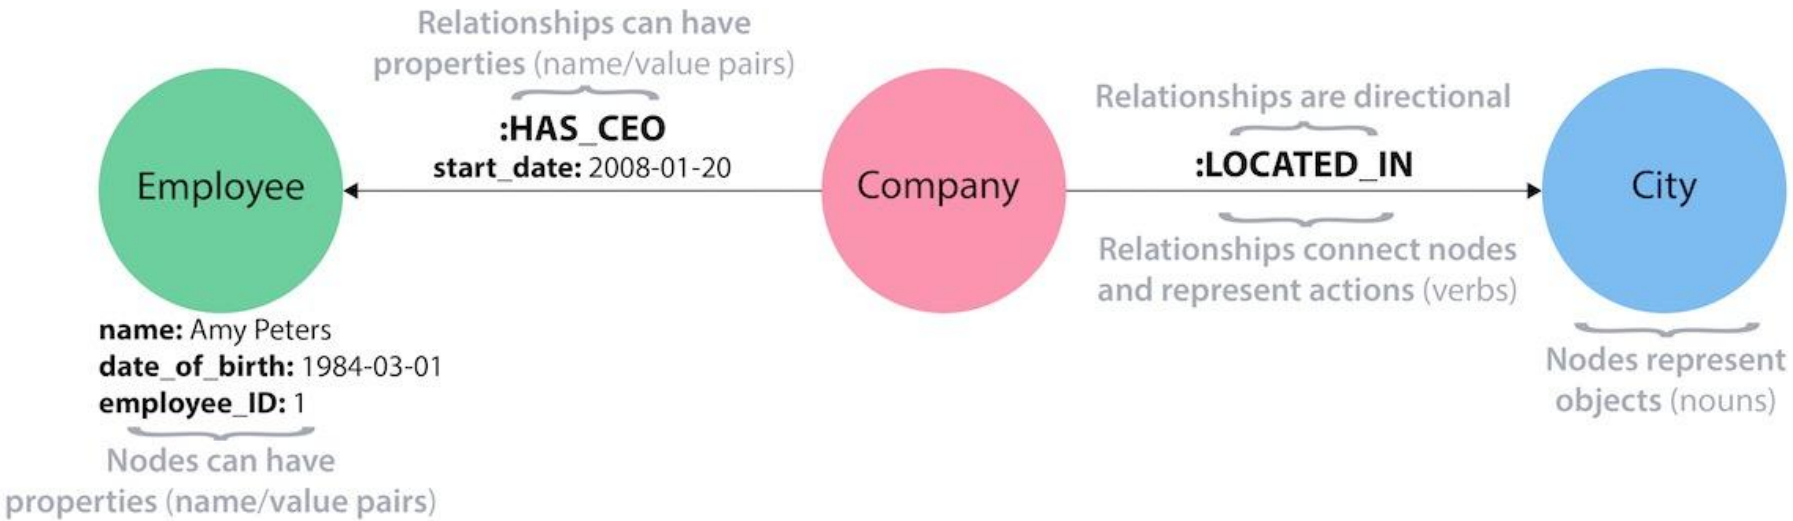
Graph model databases

- Focused on the relationship between data entities.
- Store both entities and edges between them.
- Both entities and edges can have their custom properties.
- Support querying and traversing the object graphs.
- Traversing the graph is very fast.
- For specific graph related scenarios.

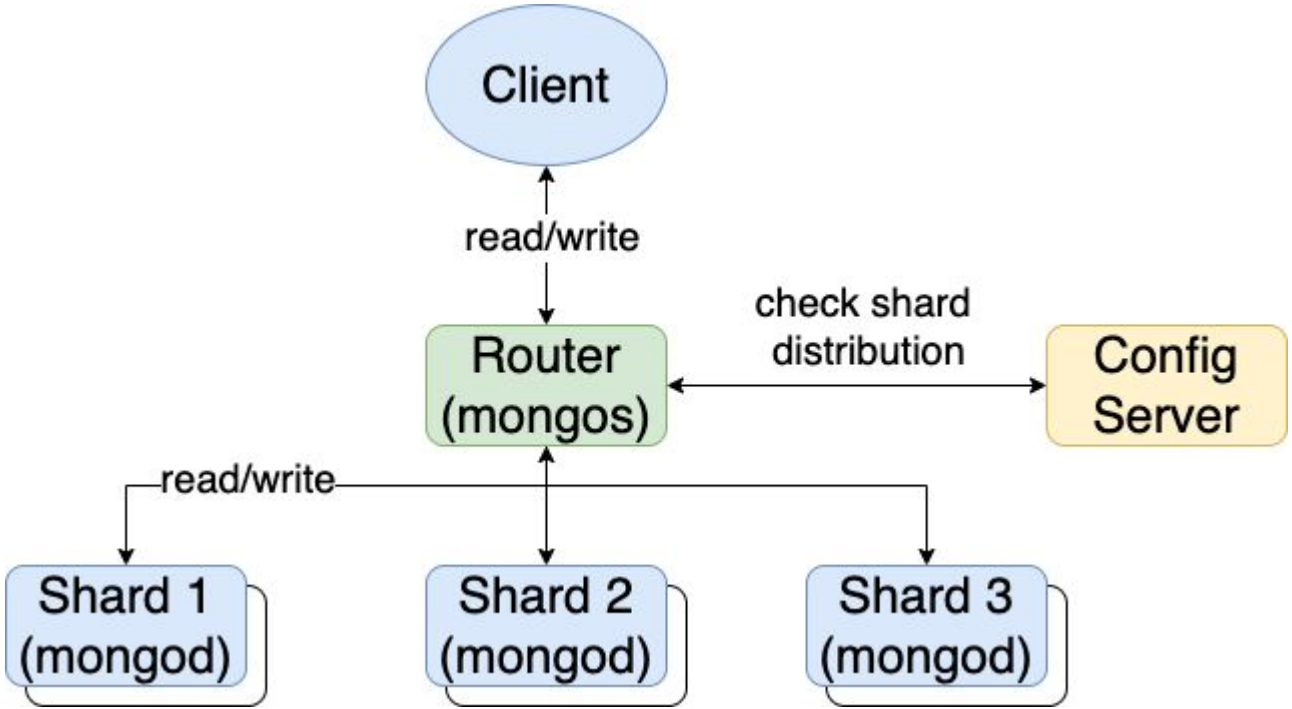


Source: neo4j.com

MongoDB

- Document oriented database - documents in JSON.
- Support for large data sets.
- Supports searching by fields, range queries and using regular expressions.
- Supports indexing/secondary indexes.
- Dedicated clients/REST API.
- Mature and production ready.

MongoDB Architecture



MongoDB Sharding

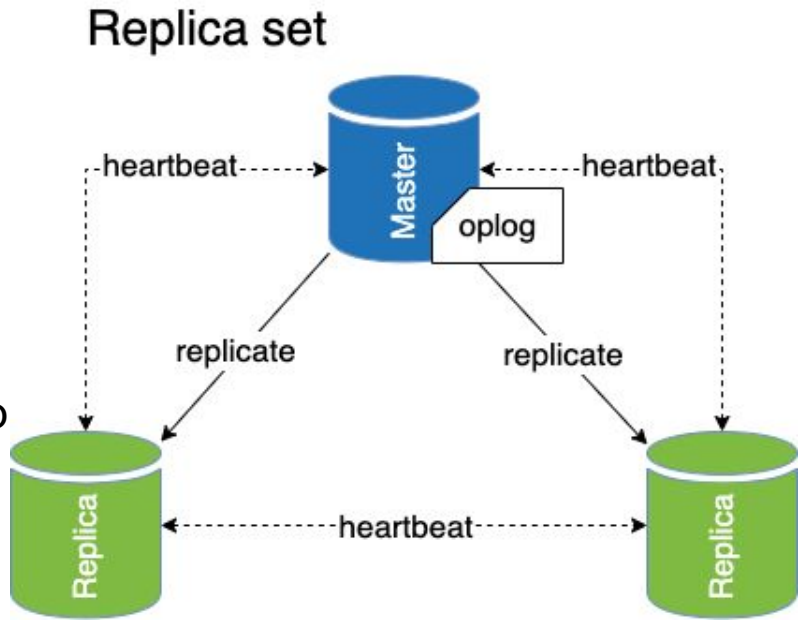
Methods of sharding:

- Range based sharding - may result in shard imbalance.
- Hash based sharding - more even value distribution.
- Tag-aware sharding - explicitly determine groups of shards on which range of documents will reside.

- Config Server will periodically assess the balance of shards across the cluster.
- Rebalance operation will move chunks between shards.
- Chunks contain adjacent values of shard keys.

MongoDB cluster replication

- Sharding is combined with replication.
- Each shard is replicated across a replica set.
- Master accepts writes which are then applied to replicas.
- Master node is determined by an election.
- To become a primary a node must be able to contact more than half of replica set.
- Election is based on priority set by administrator and timestamp of the last operation.



MongoDB Concurrency/Consistency

- Supports (since version 4.0) ACID transactions on multiple documents between shards.
- Pessimistic concurrency control at global, database, collection levels.
- Optimistic concurrency control at document level (WiredTiger storage engine).
- Consistency is tuneable.
- Write concern - the client may be ordered to write synchronously only to primary or also to a specified number of replicas - strong consistency.
- Read preference - the client may specify whether the read request is routed to primary or secondary replica.
- Read concern - the client may choose to read only replicated data that is durable or read the newest data that may not be yet replicated and thus can be lost.

MongoDB Usage Considerations

Reasons to use:

- When the strict schema is a problem.
- Use for CRUD applications, Web APIs, Content Management Systems.
- Straightforward architecture.
- Rather easy maintenance and configuration.

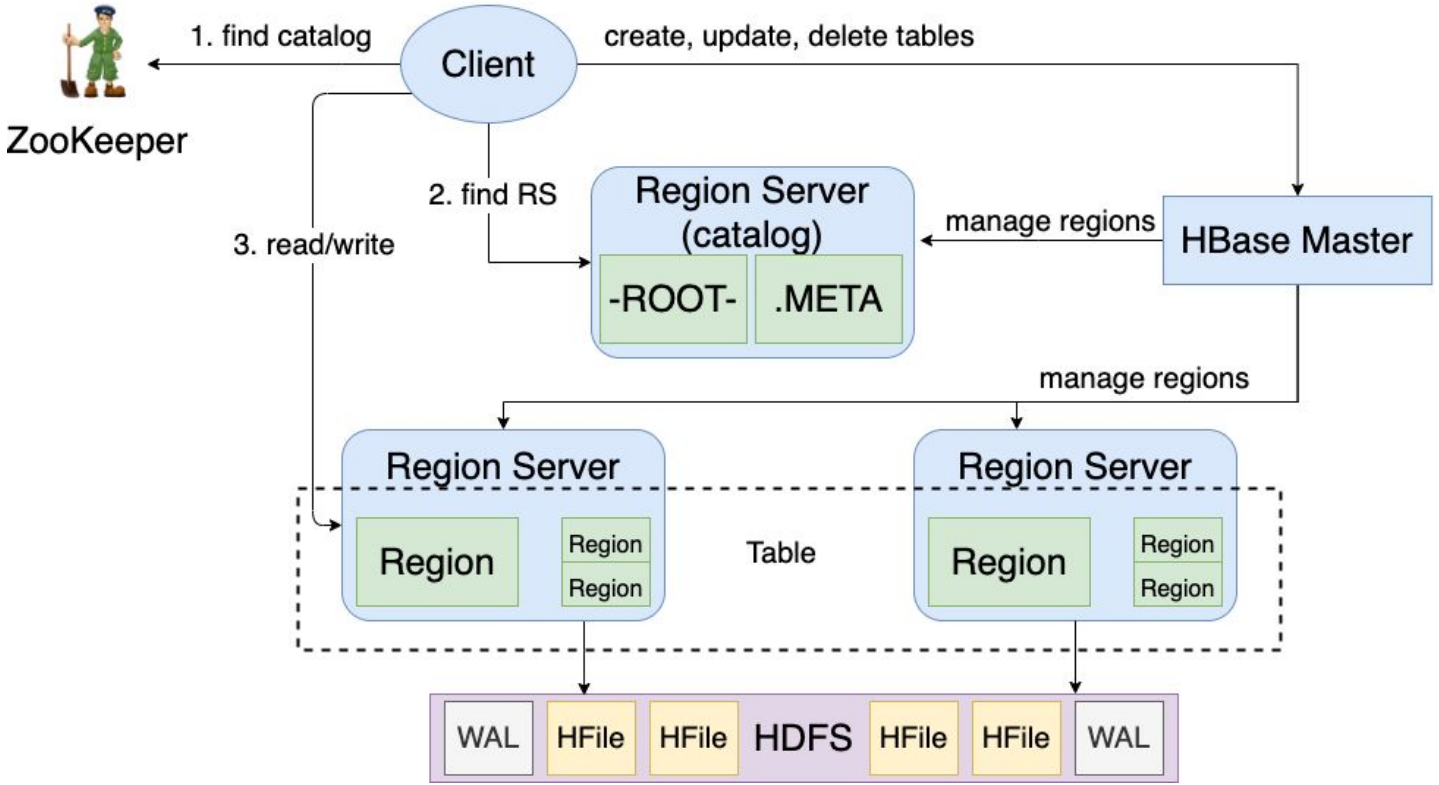
Reasons not to use:

- Be careful with relationships between documents - no constraints.
- No rigid schema is not always your friend - custom versioning patterns must be implemented by application.

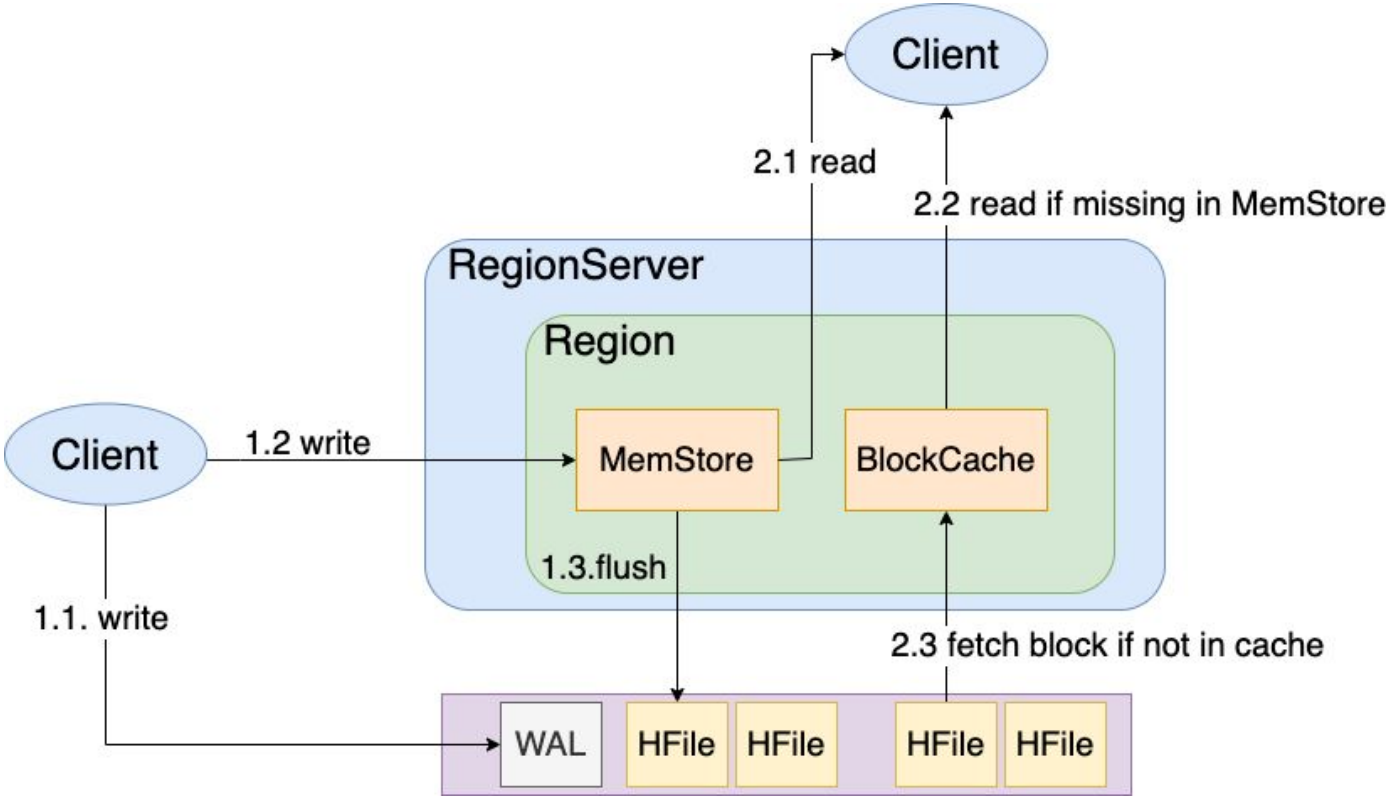
HBase

- Wide-Column oriented.
- The data model is strictly based on the original Google BigTable specification.
- Provides random access database services on top of HDFS.
- Does not bother with data redundancy or disk failures - these are handled by HDFS.
- Can be easily accessed via MapReduce jobs on Hadoop.

HBase Architecture



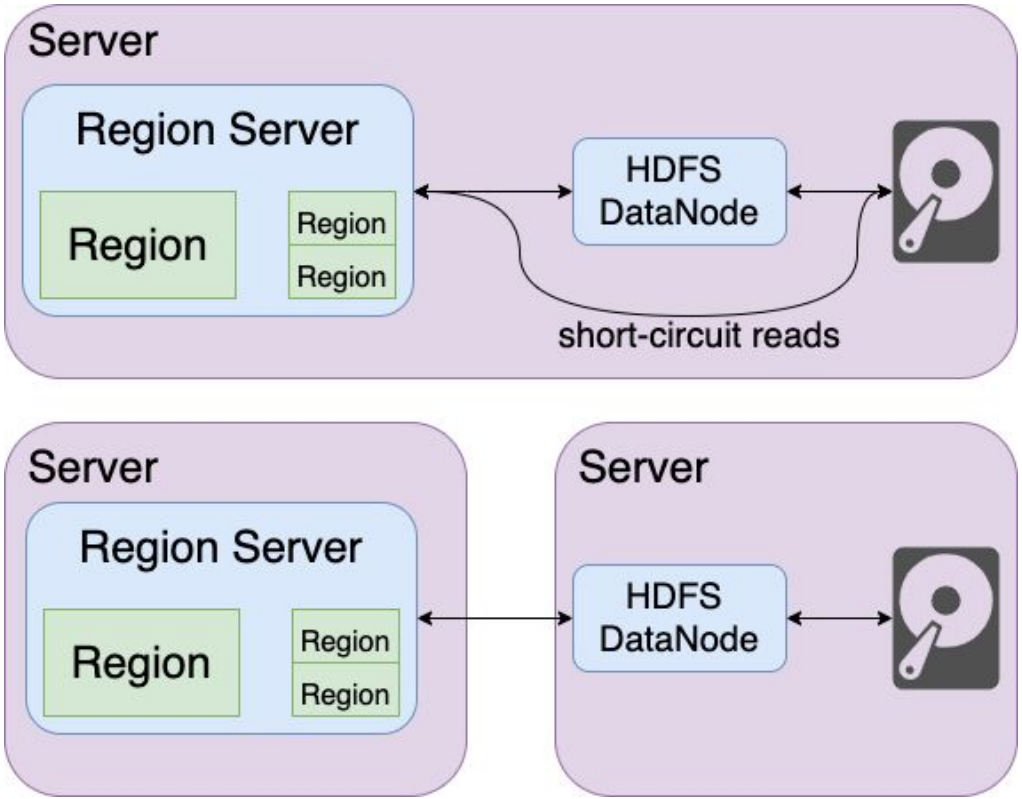
HBase Storage Architecture



HBase RegionServer

- Regions are equivalent to range based shards.
- HBase Master will evaluate the balance of regions across all RegionServers.
- Regions can be splitted when becoming too large and can be relocated to other RegionServers by the HBase Master.
- RegionServers are co-located with the Hadoop DataNodes for good data locality.
- Data locality can be broken by RegionServer rebalance, failovers.
- Data locality is usually restored when the underlying HFiles are compacted.

HBase RegionServer



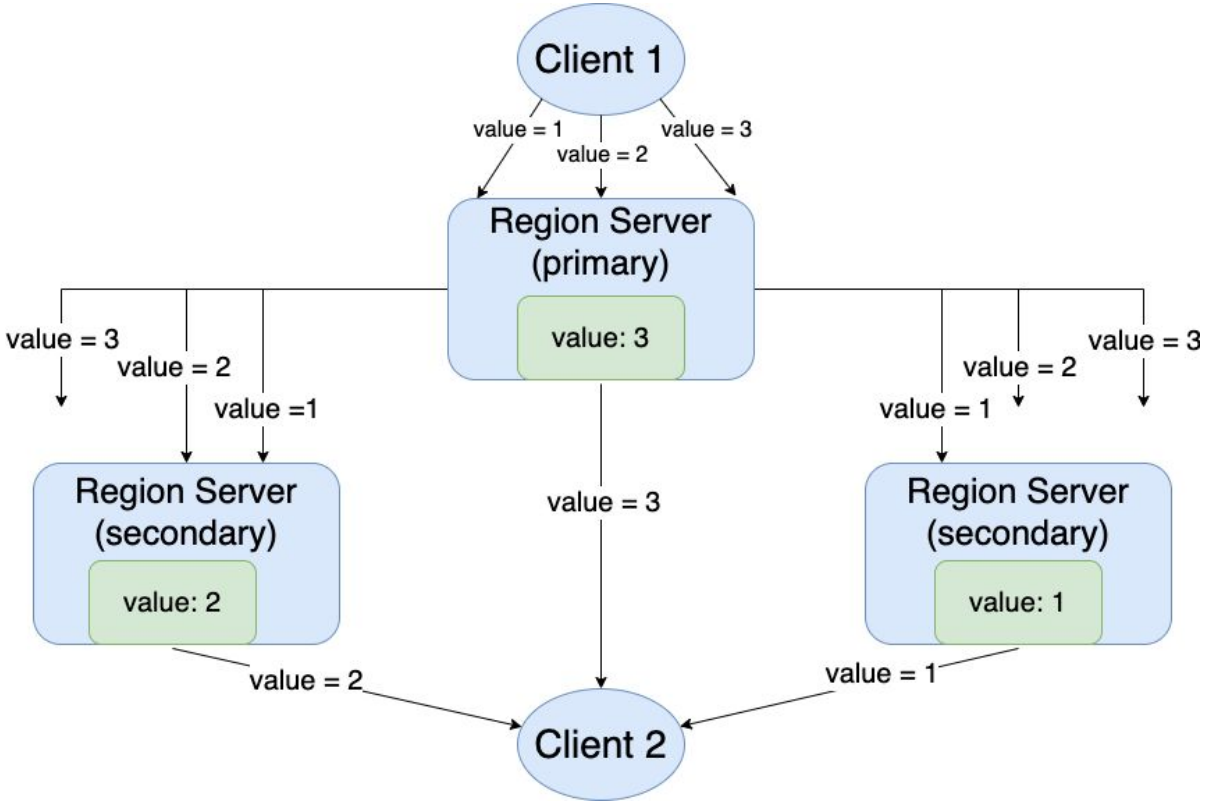
HBase Concurrency/Consistency

- No multi object transactions, only atomicity of operations at row-level.
- Row-level locking for every update, even when mutation crosses multiple Column Families.
- Reads are not blocked by write operations - concurrent read will see the previous version before update.
- Scans do not exhibit snapshot isolation, however all writes committed before the scan started will be visible, as well as those committed after.

HBase Concurrency/Consistency

- Secondary replicas for RegionServers provide availability for read operations.
- Until failover is done the affected region is only available for reads.
- Thus secondary RegionServers are read only.
- Secondary RegionServers follow the primary and see only committed updates.
- Secondary RegionServers do not make their copy of the HFiles - no storage overhead, the data is kept in BlockCache or read from primary HFiles.
- Replica RegionServers memory state can be refreshed from primary HFiles at a interval - higher chance of stale read.
- Replica RegionServers memory state can be asynchronously updated via WAL replication - lower chance of stale reads.
- Reads from replica RegionServers can be also allowed via Timeline Consistency.

HBase Timeline Consistency



HBase Usage Considerations

Reasons to use:

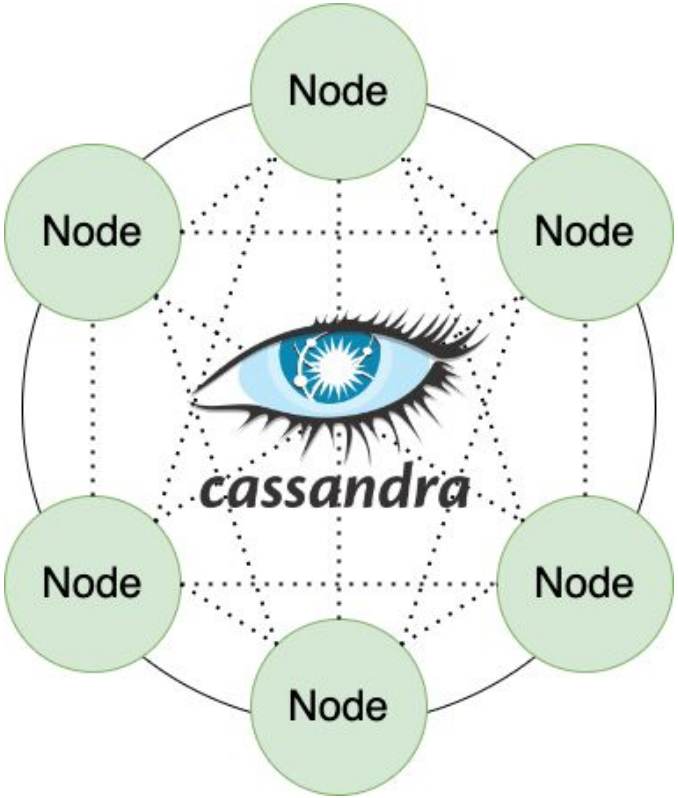
- If a true, BigTable wide column data model is required.
- If MapReduce jobs must be run on data.
- If there is an existing Hadoop/HDFS cluster.
- If there are billions of potential rows.

Reasons not to use:

- Complex multi-element architecture.
- Painful operations and maintenance.
- High performance requires a lot of memory for BlockCache.
- A myriad of dependencies for client libraries.

Cassandra

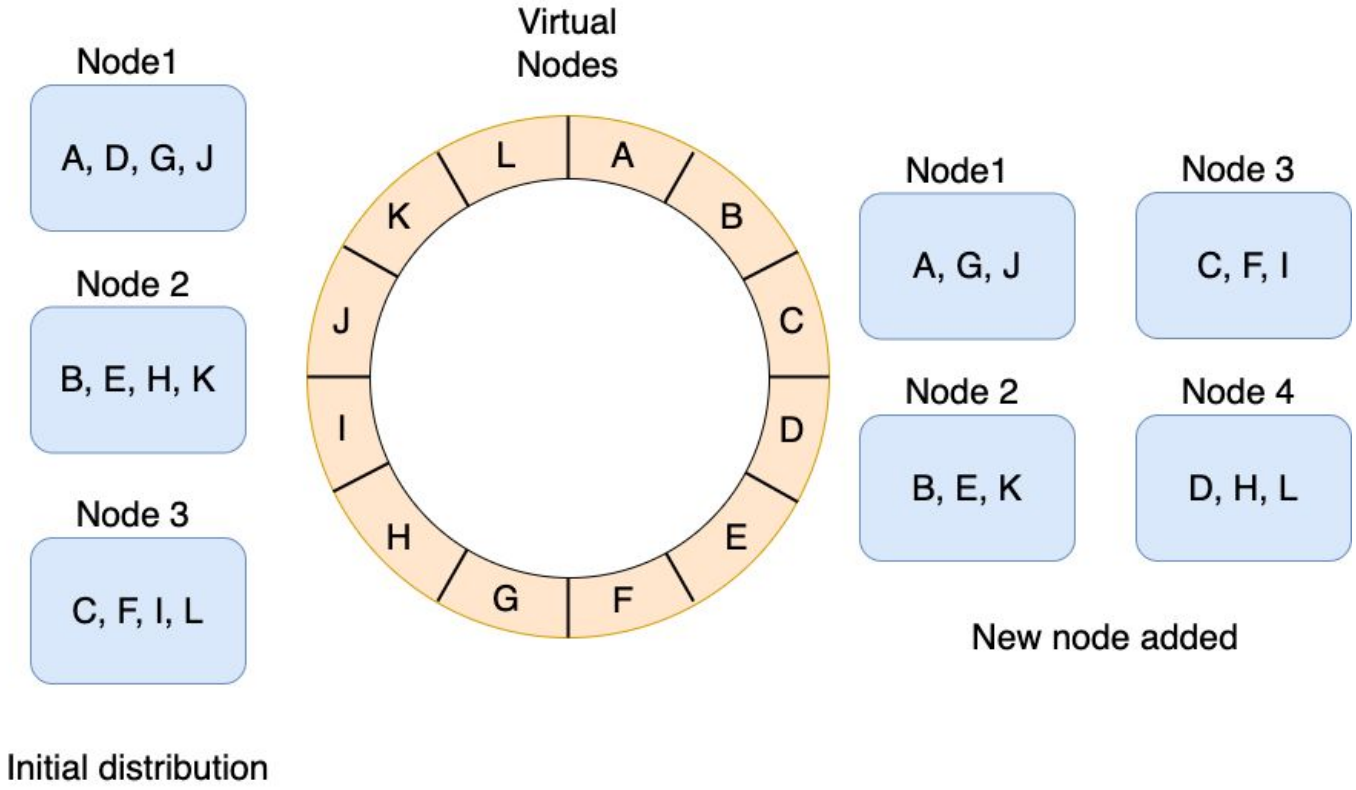
- Wide-column oriented (implicitly).
- The clustering mode is based on the concept derived from Amazon Dynamo.
- Linear scalability, you can expand the cluster or shrink horizontally whenever needed, using commodity hardware with no downtime.
- Each node in the cluster can work as a cluster coordinator and perform all operations.
- Leaderless architecture, uses gossip protocol to know the cluster state.



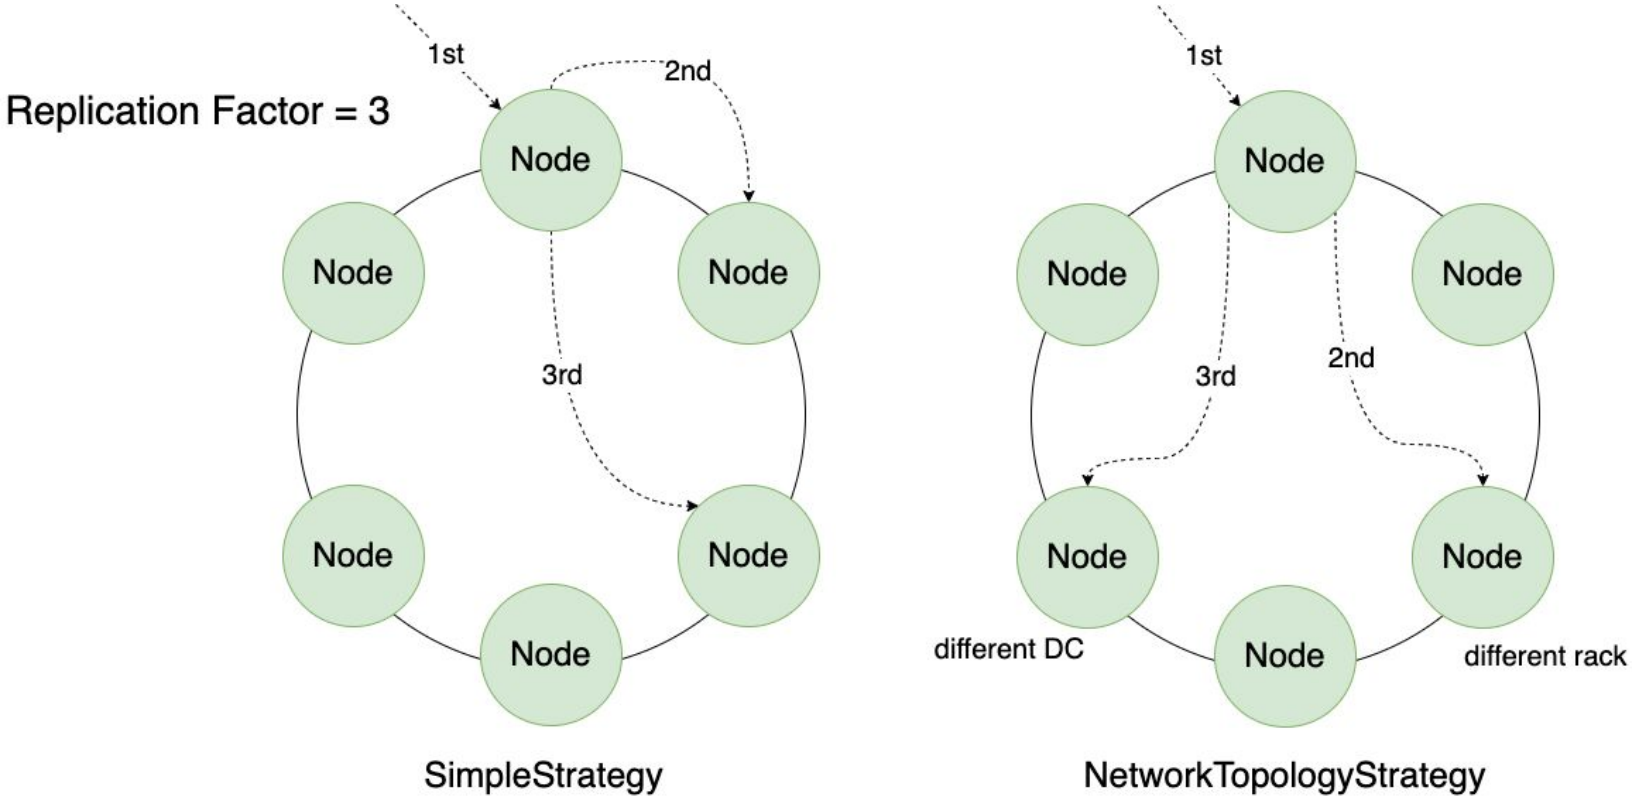
Cassandra Consistent Hashing

- Cassandra distributes data throughout the cluster by using consistent hashing technique.
- Each node is allocated a range of hash values and data is placed on the node if the primary key hash lies within the nodes range.
- If the number of ranges is equal to the number of nodes then addition or removal of node will require a lot of data movement and can result in a cluster imbalance.
- So we introduce a lot more ranges mapped to virtual nodes.
- Virtual nodes mapped to physical nodes, so that the addition/removal of node will cause few ranges to move and will leave the cluster balanced.

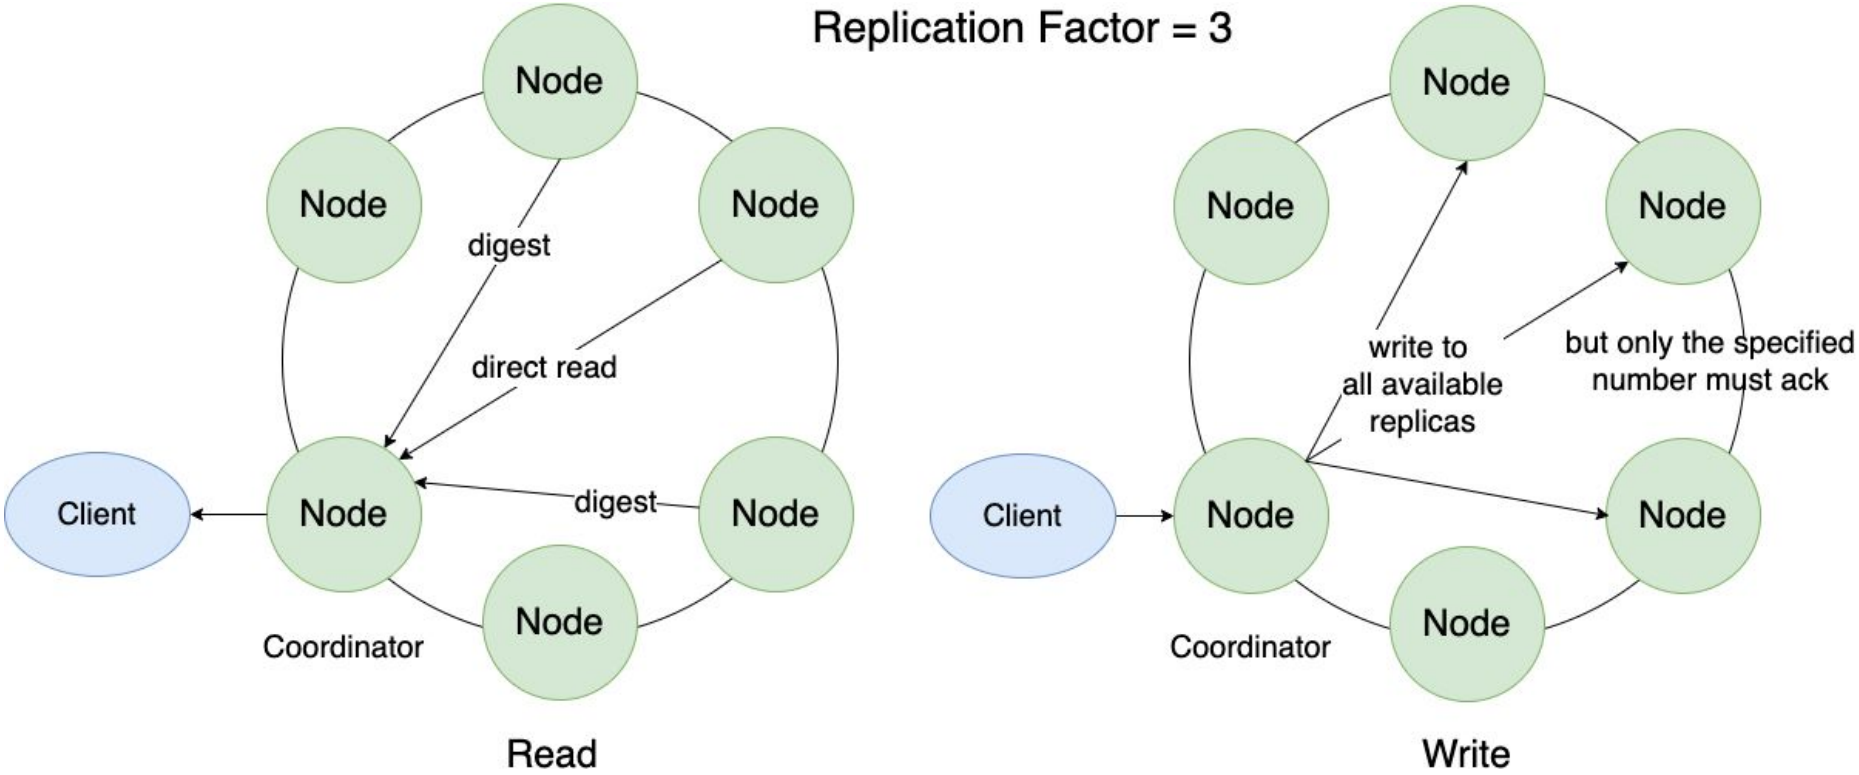
Cassandra Consistent Hashing



Cassandra Replication



Cassandra Reads/Writes



Cassandra Consistency

- Follows the Amazon Dynamo model with tunable consistency for writes and reads.
- Write Consistency levels:
  - **ALL** - all replicas must acknowledge the write.
  - **ONE\TWO\THREE** - the specified amount of nodes must acknowledge the write.
  - **QUORUM** - majority of replica nodes must acknowledge the write.
  - **ANY** - any node can acknowledge, even if the node is not responsible for storing the particular data.
- Write Consistency levels in multi DC scenario:
  - **LOCAL_QUORUM** - majority of replica nodes in a local DC must acknowledge the write.
  - **EACH_QUORUM** - majority of replica nodes in each clustered DC must acknowledge the write.

Cassandra Consistency

- Read Consistency levels:
  - **ALL** - all replica nodes are polled for the data.
  - **ONE/TWO/THREE** - reads will be polled from the specified number of replica nodes.
  - **QUORUM** - read completes after majority of nodes have returned the data.
  - **LOCAL_ONE/LOCAL_QUORUM/EACH_QUORUM** - analogous levels for multi-DC setup.

Cassandra Consistency Levels

Write\Read	ONE	QUORUM	ALL
ONE	High performance and availability, lowest consistency.	Fast writes with high availability, moderate consistency.	Fast writes with high availability, slow reads with consistency and low availability.
QUORUM	Fast and highly available reads with moderate consistency.	Medium performance, high availability and strict consistency.	Slow reads with low availability and strict consistency.
ALL	Slow writes with low availability, fast and consistent reads.	Slow writes with low availability, consistent available reads of medium performance.	Strict consistency, lowest performance and availability.

Cassandra Consistency Repair

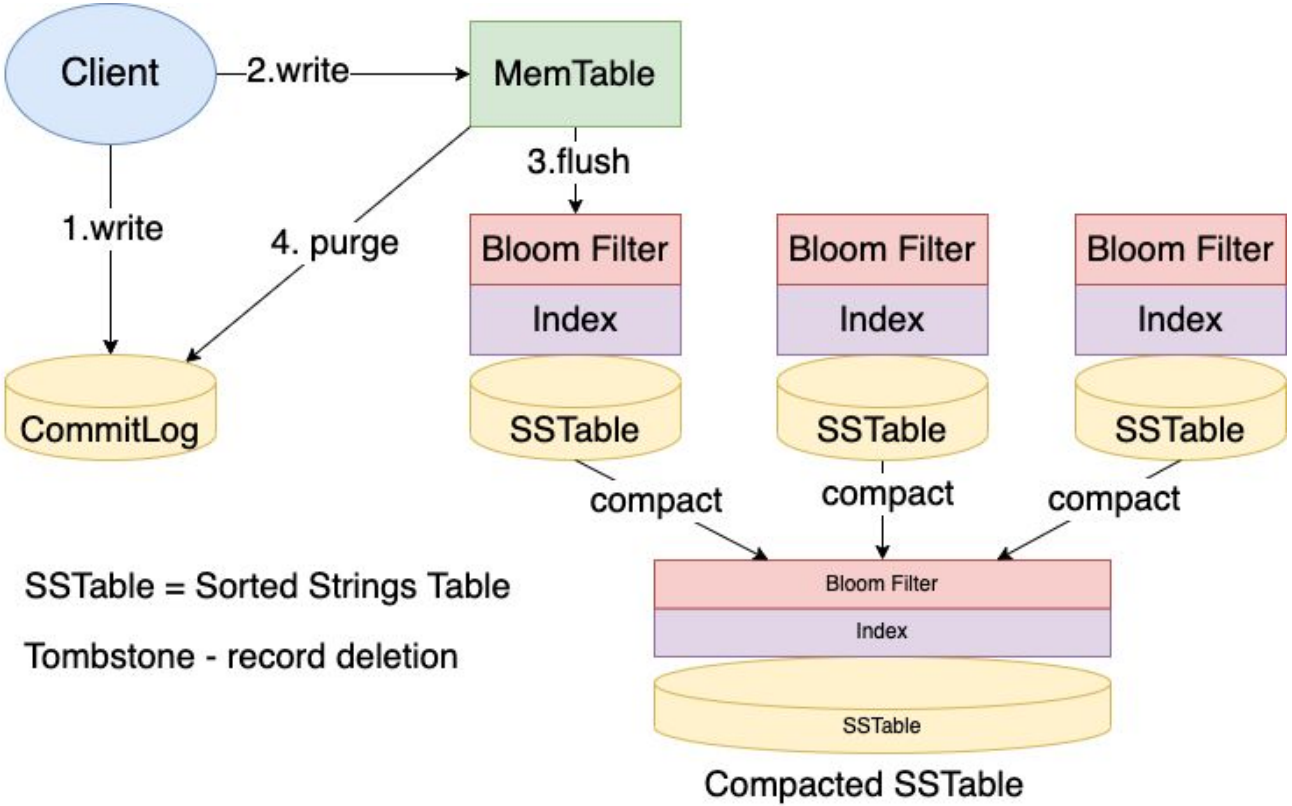
- If write consistency level is not set to ALL, inconsistencies may appear due to the node downtimes, network partitions etc.
- Hinted handoffs - a technique where a node will store an update for a temporarily unavailable replica node. If the failed node is restored, it will receive the update.
- Write consistency level ANY will write hinted handoff even if all replicas are down.
- Hinted handoffs are deleted after some time.
- Read repair - if hinted handoffs were deleted, the normal read operation may be used to repair inconsistent replicas.
- After returning the value to the client the coordinator node writes the correct data to the inconsistent replica.
- Anti-entropy repair - compares all nodes and writes most recent data to fix replicas.

Cassandra Concurrency

- The unit of modification is a single column in a row.
- Multiple clients can update separate columns in a row without a conflict.
- Conflicting writes are resolved using timestamps - “Last Write Wins”.
- Support for “lightweight”, “optimistic” transactions limited to a single operation.
- Compare-and-set - operation checks the value and if the value is as expected, updates the value, otherwise operation needs to be retried.
- Transaction implemented by a quorum based transaction protocol - Paxos:

  https://martinfowler.com/articles/patterns-of-distributed-systems/paxos.html

Cassandra Log-Structured Merge Tree



Cassandra Usage Considerations

Reasons to use:

- Applicable for most data scenarios.
- Huge datasets, accessed by “almost” SQL (no aggregate functions, no joins).
- Easy horizontal scaling, cross-DC replication.
- Leaderless architecture - increased availability.

Reasons not to use:

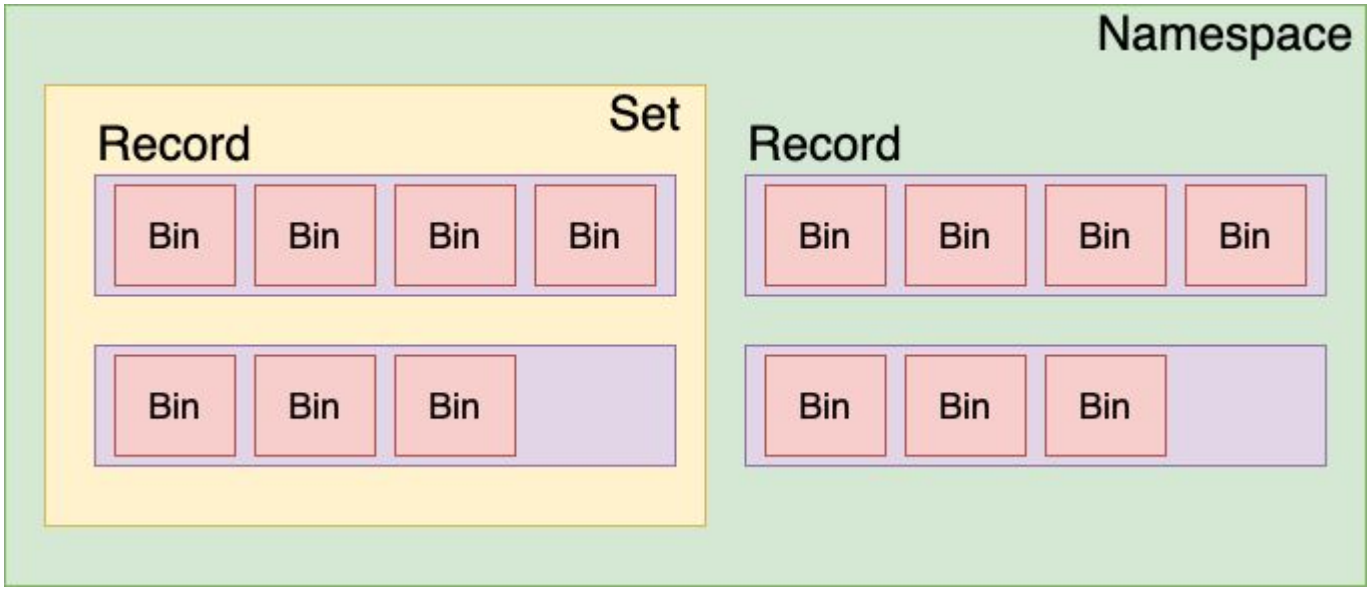
- Disk space consumption - it is difficult to tune the SSTable compaction properly in data intensive scenarios.
- Works on JVM - garbage collections, etc. may affect performance.
- Relatively complex - bugs?

Aerospike

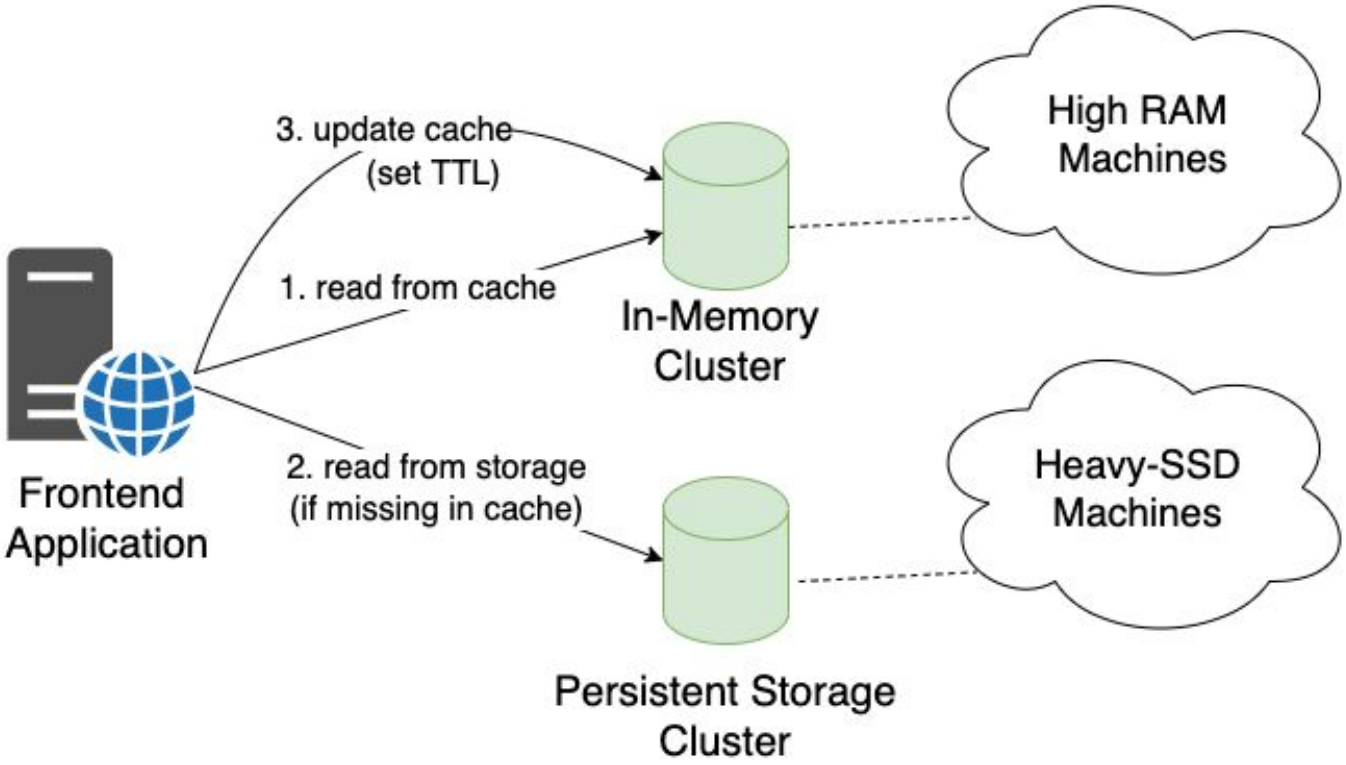
- Very fast data access by key.
- Hybrid storage - RAM + block devices + PMEM (Persistent Memory).
- Can store data on raw SSD/NVMe block device - bypassing usual filesystem layer.
- In-memory indexes preserved on a shared memory segment (for fast recovery).
- Relatively easy single master per partition replication scheme.
- Client-tunable consistency policies.
- Transactions are limited to a single record and are CAS based.

Aerospike Distribution and Data Model

- Data is always distributed into 4096 partitions, evenly spread across nodes.
- Data model is straightforward:



Aerospike Usage Scenario



Aerospike Usage Considerations

Reasons to use:

- Low latency access to data.
- High concurrency writes support.
- Easy cluster management.

Reasons not to use:

- Community version is severely limited (number of nodes, amount of data).
- Frequent scans - due to the hash based distribution model are heavy and involve all nodes.

What to store in a NoSQL Database?

- Unstructured data (images, text, binary files).
- Structured data in text document formats:
  - JSON
  - XML
- Structured data in binary formats:
  - BSON - Binary JSON
  - ProtocolBuffers
  - Apache Avro
- What we are aiming for is the forward/backward compatibility between schema versions.
- We want to support schema evolution.

Avro vs Protocol Buffers

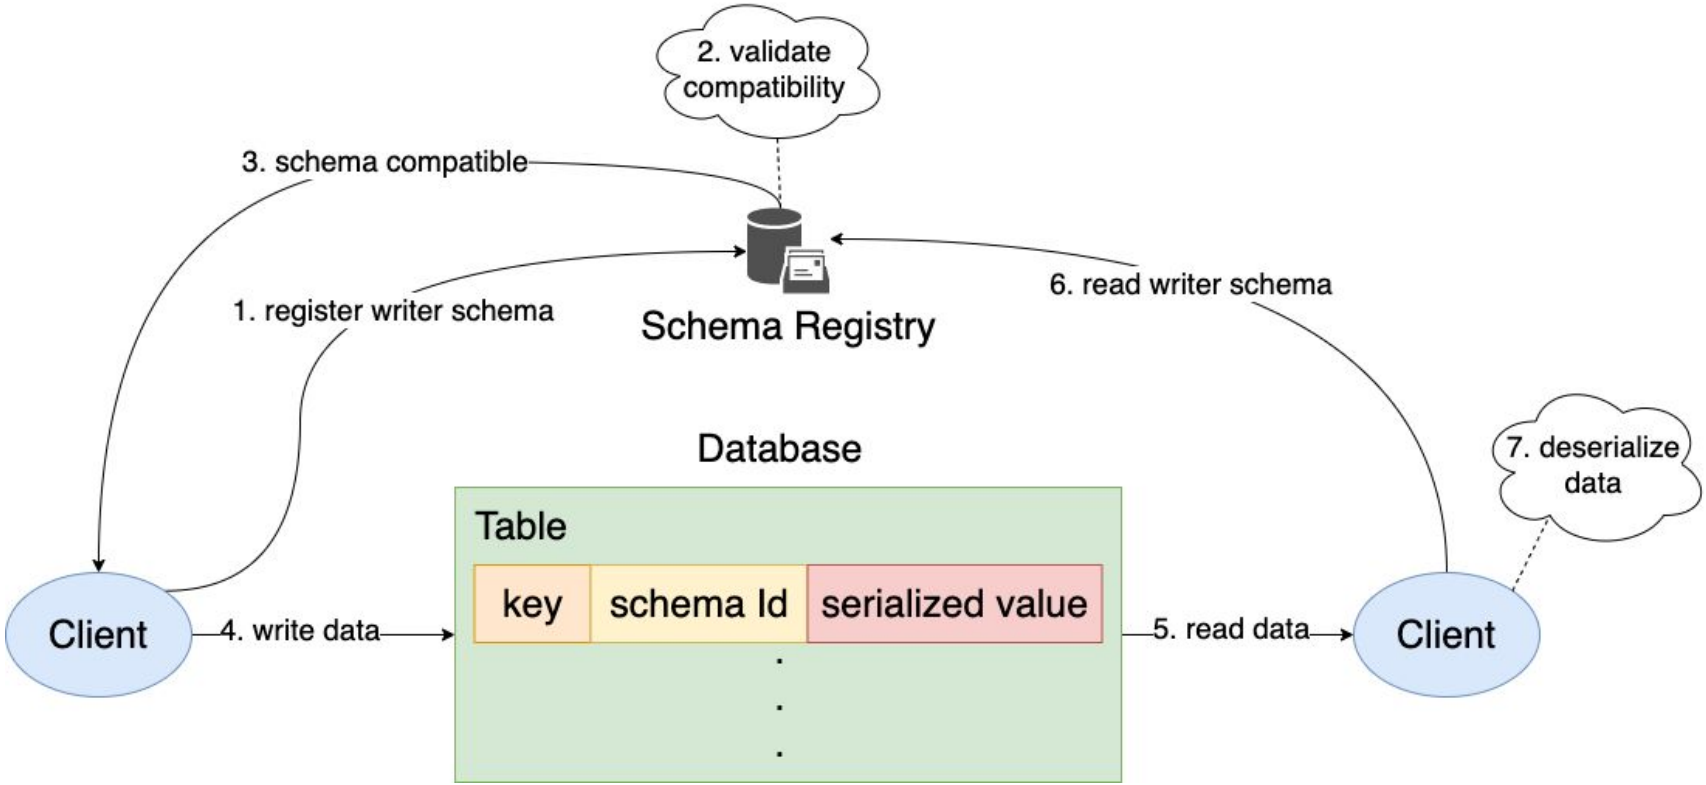
Protocol Buffers:

- Support for schema evolution via field tags (order numbers).
- Field tags cannot change and possible change of type must be compatible.
- Field tags must be written to a serialized message.
- Prevalent in various Google ecosystem tools.

Avro:

- Must know the writer schema to support the schema evolution.
- More concise binary format (no field tags).
- Wider support in various Apache Big Data tools.

Schema Registry Pattern



Summary

We have discussed:

- The available data models for NoSQL databases
- The implementation details of MongoDB, Apache HBase, Apache Cassandra and Aerospike databases.
- The data formats, schema evolution and the schema registry pattern.
